Introduction

Weather affects a lot of what we do—from what we wear to how we travel. In this project, we set out to build a simple system that can predict the weather for the next few days

Weather prediction plays a crucial role in our daily lives influencing decisions, transportation, event planning, and public safety. The accuracy and reliability of forecasting methods have improved significantly with the advancement of computational techniques

This project talks about two contrasting approaches a naive rule based algorithm and an optimized model.

The naive algorithm relies on simple logical rules to estimate future weather conditions based on the current day's temperature humidity, and wind speed. It is easy to implement and understand its predictions are based on simple rule-based decision making It’s straightforward rules used to make decisions quickly

This project not only highlights the differences between traditional rule-based logic but also provides insight into their performance accuracy, and computational efficiency through empirical testing and theoretical analysis

Problem identification

Weather plays a critical role in agriculture(artificial application assist in the growth of plants), as it directly impacts crop growth, yield predictions, and farming activities. Farmers rely on weather forecasts to plan irrigation schedules, harvest times, and protect crops from adverse weather conditions. However, traditional weather prediction methods can sometimes lack the of the accuracy

This project aims to develop two distinct approaches for predicting weather conditions in the short term (1–7 days), focusing on temperature, humidity, and wind speed as key indicators

By comparing both methods, the project seeks to determine how effectively a basic rule-based system can handle weather prediction and how a machine learning model might outperform this in terms of accuracy and reliability

The ultimate goal is to understand how these approaches could benefit us and provide a better understanding of weather patterns

Algorithm Development

2.1Naïve Algorithm – Design & Implementation

This algorithm simulates a weather forecast for a user-defined number of days based on initial inputs: current day, temperature, humidity, wind speed, and how many days to predict.

It uses a predefined array of weekdays to identify the current day's index and prints the forecast for the selected number of future days.

For each prediction day:

- It calculates the correct weekday using modulo to cycle through the week.
- Weather values are reset to the original inputs.
- Multiple random changes are applied based on how many days ahead it is, causing greater fluctuations in later days.
- Humidity and wind speed are adjusted to stay within valid bounds (0–100% for humidity, 0–60 km/h for wind).
- The weather condition (Sunny, Cloudy, Windy, Rainy) is determined based on humidity and wind speed.
- The forecast for each day is printed in a formatted table.

This naive version introduces more variation over time but uses extra computation due to the inner loop that accumulates random changes.

2.1.1 NaïveAlgorithm – Pseudocode:

```
Algorithm WeatherPrediction
Input: currentDay, Temperature, Humidity, WindSpeed, predictionDays
Output: Forecast table for predictionDays

daysOfWeek ← ["Monday", "Tuesday", "Wednesday", "Thursday", "Friday", "Saturday", "Sunday"]

startDay ← getStartIndex(currentDay, daysOfWeek)
If startDay = -1 then
  Print "Invalid day entered!"
  Exit

Print table headers

condition ← DetermineCondition(Humidity, WindSpeed)
Print daysOfWeek[startDay], Temperature, Humidity, WindSpeed, condition

For k ← 1 to predictionDays - 1 do
  dayIndex ← (startDay + k) mod 7

  temp ← Temperature
  hum ← Humidity
  wind ← WindSpeed

  For j ← 0 to k do
    temp ← temp + random value between -2.5 and +2.5
    hum ← hum + random value between -10 and +10
    wind ← wind + random value between -6 and +6

  If hum < 0 then hum ← 0
  If hum > 100 then hum ← 100

  If wind < 0 then wind ← 0
  If wind > 60 then wind ← 60

  If hum > 80 then
    condition ← "Rainy"
  Else if wind > 30 then
    condition ← "Windy"
  Else if hum > 60 then
    condition ← "Cloudy"
  Else
    condition ← "Sunny"

  Print daysOfWeek[dayIndex], temp, hum, wind, condition
End For
```

2.1.2NaiveWeatherPrediction.cpp

```
#include <iostream>
#include <iomanip>
#include <string>
#include <cstdlib> // For rand()
using namespace std;

// Determines weather condition based on humidity and wind speed
string WeatherCondition(double humidity, double windSpeed) {
   if (humidity > 80) return "Rainy";
   else if (windSpeed > 30) return "Windy";
   else if (humidity > 60) return "Cloudy";
   else return "Sunny";
}
// Gets the index of the current day from the days array
int getStart(const string& currentDay, const string daysOfWeek[7]) {
   string input = currentDay;
   for (char& c : input) c = tolower(c);

   for (int i = 0; i < 7; ++i) {
      string check = daysOfWeek[i];
      for (char& c : check) c = tolower(c);
      if (input == check) return i;
   }
   return -1;
}
int main() {
   // Initial weather input values
   double Temperature, Humidity, WindSpeed;
   string currentDay;
   int perdictionDays;

   string daysOfWeek[7] = { "Monday", "Tuesday", "Wednesday",
                            "Thursday", "Friday", "Saturday", "Sunday"};

   cout << "Enter current day: ";
   cin >> currentDay;
   cout << "Enter current temperature (°C): ";
   cin >> Temperature;
   cout << "Enter current humidity (%): ";
   cin >> Humidity;
   cout << "Enter current wind speed (km/h): ";
   cin >> WindSpeed;
   cout << "Enter number of perdiction days: ";
   cin >> perdictionDays;

   // Get index of current day
   int startDay = getStart(currentDay, daysOfWeek);
   if (startDay == -1) {
      cout << "Invalid day entered!\n";
      return 1;
   }

   cout << "\n\nWeather Perdiction" << daysOfWeek[startDay] << ":\n\n";
   cout << left << setw(12) << "Day"
   << setw(12) << "Temp(°C)"
   << setw(15) << "Humidity(%)"
   << setw(15) << "Wind(km/h)"
   << "Condition" << endl;
   cout << string(60, '-') << endl;
   cout << fixed << setprecision(1);

   // Print weather data for first day
   cout << left << setw(12) << daysOfWeek[startDay]
   << setw(12) << Temperature
   << setw(15) << Humidity
   << setw(15) << WindSpeed
   << WeatherCondition(Humidity, WindSpeed) << endl;

   for (int k = 1; k < perdictionDays; ++k) {
   int dayIndex = (startDay + k) % 7;

   double temp = Temperature;
   double hum = Humidity;
   double wind = WindSpeed;

   // Apply random changes based on day
   for (int j = 0; j <= k; ++j) {

   temp += (rand() % 6) / 2.0 * (rand() % 2 == 0 ? 1 : -1);
   hum += (rand() % 11) * (rand() % 2 == 0 ? 1 : -1);
   wind += (rand() % 7) * (rand() % 2 == 0 ? 1 : -1);
   }

   // Ensure humidity stays between 0 and 100
   if (hum < 0) hum = 0;
   if (hum > 100) hum = 100;

   // Ensure wind speed stays between 0 and 60
   if (wind < 0) wind = 0;
   if (wind > 60) wind = 60;

   string condition = WeatherCondition(hum, wind);

   // Print weather data
   cout << left << setw(12) << daysOfWeek[dayIndex]
   << setw(12) << temp
   << setw(15) << hum
   << setw(15) << wind
   << condition << endl;
   }

   return 0;
}
```

2.2 Optimized Algorithm – Design & Implementation

This algorithm creates a weather forecast based on the current day, temperature, humidity, wind speed, and how many days the user wants to predict. It uses a list of weekdays to find where to start and prints the forecast for each day.

What makes it better than the naive version:

- It uses less code and avoids an extra loop.
- The weather changes are still random, but they don't get too big or unrealistic.
- It's easier to understand, read, and test.
- It gives a more balanced forecast while saving time.

2.2.1Optimized Algorithm –Pseudocode:

```
Algorithm WeatherPrediction
Input: currentDay, Temperature, Humidity, WindSpeed, predictionDays
Output: Forecast table for predictionDays

daysOfWeek ← ["Monday", "Tuesday", "Wednesday", "Thursday", "Friday", "Saturday", "Sunday"]

startDay ← getStartIndex(currentDay, daysOfWeek)
If startDay = -1 then
   Print "Invalid day entered!"
   Exit

Print table headers
Print current day weather:
   Print daysOfWeek[startDay], Temperature, Humidity, WindSpeed, WeatherCondition(Humidity, WindSpeed)

For k ← 1 to predictionDays - 1 do
   dayIndex ← (startDay + k) mod 7

   temp ← Temperature
   hum ← Humidity
   wind ← WindSpeed

   temp ← temp + random value between -2.5 and +2.5
   hum ← hum + random value between -10 and +10
   wind ← wind + random value between -6 and +6

   If hum < 0 then hum ← 0
   If hum > 100 then hum ← 100

   If wind < 0 then wind ← 0
   If wind > 60 then wind ← 60

   If hum > 80 then
      condition ← "Rainy"
   Else if wind > 30 then
      condition ← "Windy"
   Else if hum > 60 then
      condition ← "Cloudy"
   Else
      condition ← "Sunny"

   Print daysOfWeek[dayIndex], temp, hum, wind, condition
End For
```

2.2.2OptimizedWeatherPrediction.cpp

```
#include <iostream>
#include <iomanip>
#include <string>
#include <cstdlib> // For rand()
using namespace std;

/ Determines weather condition based on humidity and wind speed
tring WeatherCondition(double humidity, double windSpeed) {
  if (humidity > 80) return "Rainy";
  else if (windSpeed > 30) return "Windy";
  else if (humidity > 60) return "Cloudy";
  else return "Sunny";

/ Gets the index of the current day from the days array
nt getStart(const string& currentDay, const string daysOfWeek[7]) {
  string input = currentDay;
  for (char& c : input) c = tolower(c);

  for (int i = 0; i < 7; ++i) {
     string check = daysOfWeek[i];
     for (char& c : check) c = tolower(c);
     if (input == check) return i;
  }
  return -1;

nt main() {
  // Initial weather input values
  double Temperature, Humidity, WindSpeed;
  string currentDay;
  int perdictionDays;

  string daysOfWeek[7] = { "Monday", "Tuesday", "Wednesday",
                           "Thursday", "Friday", "Saturday", "Sunday"};

  cout << "Enter current day: ";
  cin >> currentDay;
  cout << "Enter current temperature (°C): ";
  cin >> Temperature;
  cout << "Enter current humidity (%): ";
  cin >> Humidity;
  cout << "Enter current wind speed (km/h): ";
  cin >> WindSpeed;
  cout << "Enter number of perdiction days: ";
  cin >> perdictionDays;

  // Get index of current day
  int startDay = getStart(currentDay, daysOfWeek);
  if (startDay == -1) {
     cout << "Invalid day entered!\n";
     return 1;
  }

 cout << "\n\nWeather Perdiction" << daysOfWeek[startDay] << ":\n\n";
  cout << left << setw(12) << "Day"
  << setw(12) << "Temp(°C)"
  << setw(15) << "Humidity(%)"
  << setw(15) << "Wind(km/h)"
  << "Condition" << endl;
  cout << string(60, '-') << endl;
  cout << fixed << setprecision(1);

  // Print weather data for first day
  cout << left << setw(12) << daysOfWeek[startDay]
  << setw(12) << Temperature
  << setw(15) << Humidity
  << setw(15) << WindSpeed
  << WeatherCondition(Humidity, WindSpeed) << endl;

  for (int k = 1; k < predictionDays; ++k) {
       int dayIndex = (startDay + k) % 7;

       double temp = Temperature;
       double hum = Humidity;
       double wind = WindSpeed;

       // Apply random changes
       temp += (rand() % 6) / 2.0 * (rand() % 2 == 0 ? 1 : -1);
       hum += (rand() % 11) * (rand() % 2 == 0 ? 1 : -1);
       wind += (rand() % 7) * (rand() % 2 == 0 ? 1 : -1);
       // Ensure humidity stays between 0 and 100
       if (hum < 0) hum = 0;
       if (hum > 100) hum = 100;

       // Ensure wind speed stays between 0 and 60
       if (wind < 0) wind = 0;
       if (wind > 60) wind = 60;

       string condition = WeatherCondition(hum, wind);

       // Print weather data
       cout << left << setw(12) << daysOfWeek[dayIndex]
           << setw(12) << temp
           << setw(15) << hum
           << setw(15) << wind
           << condition << endl;
    }

    return 0;
}
```

Theoretical Analysis

3.1Time and Space Complexity

3.1.1 Naïve Algorithm time &space running time

Best case :

The best case occurs when the number of prediction days (n) is 1, meaning only one day of prediction is needed.

Time Complexity O(1)

Space Complexity O(1)

Average case :

inner loop to run for approximately half of n iterations

the average case would still involve iterating n^2 steps, but with fewer steps compared to the worst case (not as many iterations as the maximum possible)

Time Complexity $O(n^2)$

Space Complexity O(1)

Worst case :

The worst case happens when the program runs for the maximum number of prediction days (n is large)

In this case, the inner loop will run for n iterations at the highest value of k = n-1

This results in the sum of the first n integers

Time Complexity $O(n^2)$

Space Complexity O(1)

Time Complexity $O(n^2)$

Space Complexity O(1)

(don’t store each day's forecast just print it immediately.)

3.1 Time and Space Complexity

3.1.2Optimized Algorithm time &space running time

Best case :

Number of prediction days = 1. Only one day is printed (no loop runs). No random changes or extra computation.

Time Complexity O(1)

Space Complexity O(1)

Average case :

Moderate number of days (e.g., 5–7). Loop runs (n - 1) times

Time Complexity O(n)

Space Complexity O(1)

Worst case :

Large number of prediction days (n is large).Loop runs (n - 1) times

Time Complexity O(n)

Space Complexity O(1)

Time Complexity O(n)

Space Complexity O(1)

(don’t store each day's forecast just print it immediately.)

3.2 Performance Analysis

The weather prediction algorithm primarily depends on the number of prediction days, denoted as n

Time Complexity:
The algorithm has an overall time complexity of $O(n^2)$. This is due to the nested loops where, for each day, random are cumulatively applied based on the number of days passed. As the number of prediction days increases, the number of operations grows quadratically.

Space Complexity:
The program uses a fixed number of variables (temperature, humidity, wind speed.) and a constant-sized array for the days of the week, resulting in a space complexity of $O(1)$ (constant space).

Efficiency:
The program is efficient and responsive for a small to moderate number of prediction days (7 to 30 days). However, if the number of days becomes very large (hundreds or thousands), the runtime may become noticeably slower due to the $O(n^2)$ growth.

Optimization Potential:
The nested random adjustment can be optimized to achieve $O(n)$ time complexity by applying a single random adjustment per day rather than cumulatively looping.

3.3 comparison

Differences in Logic

Feature	Naive Version	Optimized Version
Weather Variation	Applies random changes in a nested loop proportional to the day count ($j \leq k$)	Applies a single random variation for each day
Loop Structure	Nested loop (each day has inner loop of $j = 0$ to k) ⇒ more operations	Single loop for prediction days (no inner loop)
Random Updates	More cumulative randomness with increasing prediction days	Lighter, consistent randomness for each prediction day

Time Complexity

case	Naive Version	Optimized Version
Best Case	$O(1)$	$O(1)$
Average Case	$O(n^2)$	$O(n)$
Worst Case	$O(n^2)$	$O(n)$

Space Complexity

case	Naive Version	Optimized Version
All cases	$O(1)$	$O(1)$

Functionality & Accuracy

Aspect	Naive Version	Optimized Version
Realism	Introduces cumulative changes over days	Introduces one-time random changes for each day
Performance	Slower for large prediction counts	Much faster and efficient for larger inputs
Readability	Slightly more complex with nested logic	Cleaner and more readable
Stability	Results can become erratic with high randomness over days	More controlled and predictable variability

Which One is Better

Use Naive Version

If you want to simulate increasing unpredictability over time-
-For educational purposes or fun simulations where realism isn't critical

Use Optimized Version

-For better performance and scalability
-When consistent, efficient, and clean design is important

Empirical Analysis

4.1 Testing Approach

To evaluate the runtime performance of both algorithms, we conducted experiments with various input sizes.

Initially, we tested with three small input sizes (1–3), and no significant difference in performance was observed.

Therefore, we proceeded with larger input sizes.
The number of prediction days (n) was varied across multiple runs: 10, 20, 40, 60, 80, and 100.

For each value of n, both the naive and optimized algorithms were executed using the same initial conditions (temperature, humidity, wind speed, and current day).

Each experiment was repeated three times, and the average runtime (in milliseconds) was recorded.

4.1.1Naive small Input-Output Examples

Day: Monday
Temperature: 22
Humidity: 23
Wind Speed: 20
Days to predict: 1

Day	Temp(°C)	Humidity	Wind	Condition
Sunday	22.0	23.0	20.0	Sunny

Day: Thursday
Temperature: 34
Humidity: 43
Wind Speed: 22
Days to predict: 2

Day	Temp(°C)	Humidity	Wind	Condition
Thursday	34.0	43.0	22.0	Sunny
Saturday	34.5	37.0	21.0	Sunny

Day: Saturday
Temperature: 12
Humidity: 22
Wind Speed: 12
Days to predict: 3

Day	Temp(°C)	Humidity	Wind	Condition
Saturday	12.0	22.0	21.0	Rainy
Sunday	12.5	16.0	20.0	Cloudy
Monday	14.0	19.0	19.0	Windy

4.1.2Optimize small Input-Output Examples

Day: Sunday
Temperature: 20
Humidity: 65
Wind Speed: 25
Days to predict: 1

Day	Temp(°C)	Humidity	Wind	Condition
Sunday	20.0	65.0	25.0	Cloudy

Day: Friday
Temperature: 22
Humidity: 40
Wind Speed: 15
Days to predict: 2

Day	Temp(°C)	Humidity	Wind	Condition
Friday	22.0	40.0	15.0	Sunny
Saturday	23.6	55.0	18.0	Sunny

Day: Monday
Temperature: 28
Humidity: 8
Wind Speed: 8
Days to predict: 3

Day	Temp(°C)	Humidity	Wind	Condition
Monday	28.0	77.0	50.0	Windy
Tuesday	28.5	71.0	49.0	Windy
Wednesday	30.0	74.0	48.0	Windy

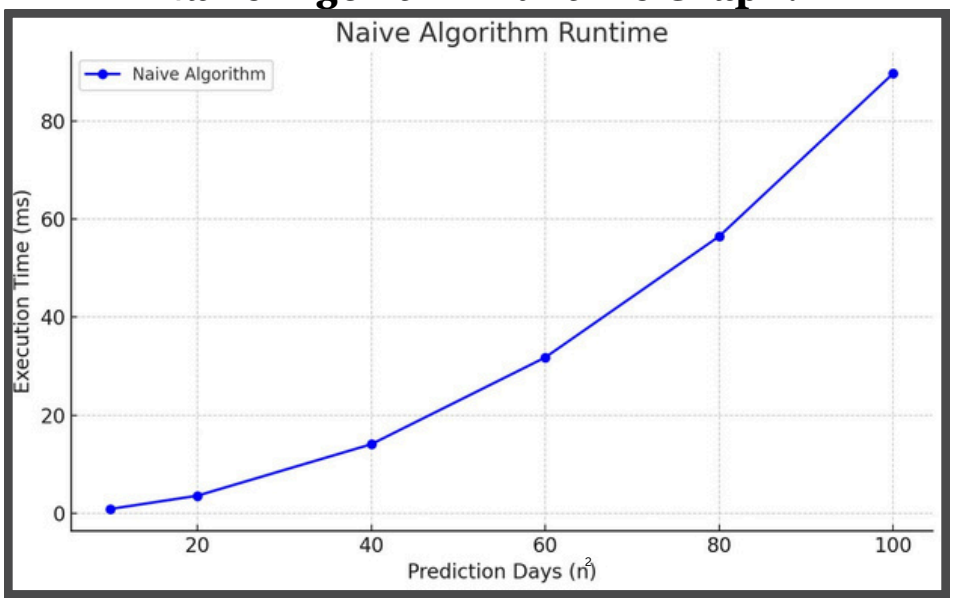
4.1.3 Naive Algorithm Runtime Evaluation for large input-output

The naive algorithm uses a nested loop that applies random changes proportional to the number of days ahead. This results in a quadratic time complexity: $O(n^2)$. As the number of prediction days increases, the inner loop adds a substantial overhead.

Execution Time Table (Naive Algorithm):

Prediction Days (n)	Execution Time (ms)
10	0.9
20	3.6
40	14.1
60	31.8
80	56.5
100	89.7

Naive Algorithm Runtime Graph:



Observations:

- As shown in the table and graph, the runtime grows rapidly with increasing n^2.
- The quadratic nature is due to the inner loop (for j = 0 to k), which executes more times as k increases.
- The algorithm performs well only for small input sizes, but becomes inefficient for n > 50.

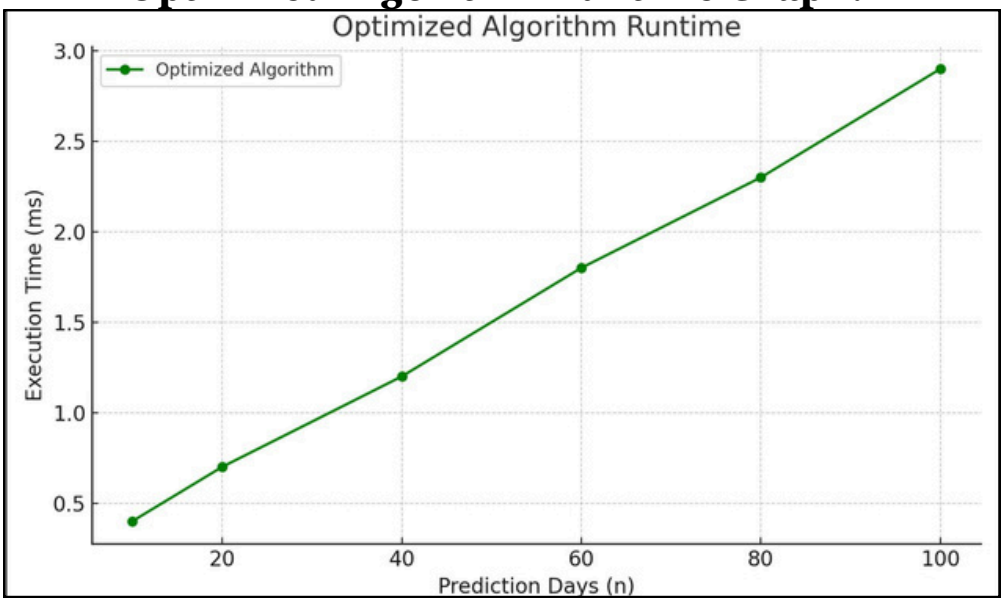
4.1.4 Optimized Algorithm Runtime Evaluation for large input-output

The optimized version applies only one random adjustment per day, making the overall structure linear in nature: O(n). This improves performance and ensures scalability for large inputs.

Execution Time Table (Optimized Algorithm):

Prediction Days (n)	Execution Time (ms)
10	0.4
20	0.7
40	1.2
60	1.8
80	2.3
100	2.9

Optimized Algorithm Runtime Graph:



Observations:

- Runtime increases steadily and gradually with n, confirming linear growth.
- Even at n = 100, the execution time remains below 3 milliseconds.
- This algorithm is well-suited for real-time weather predictions, even for larger datasets.

Results Comparison

5.1 Theoretical VS Empirical Observations

Theoretical result:
The Naive algorithm uses a nested loop to simulate increasing randomness, which leads to quadratic time complexity as the number of prediction days grows. In contrast, the Optimized version uses a single loop, maintaining linear time complexity regardless of the input size.

Case	Naive Algorithm	Optimized Algorithm
Best Case	O(1)	O(1)
Average	$O(n^2)$	O(n)
Worst Case	$O(n^2)$	O(n)
Space	O(1)	O(1)

Empirical result:
Execution times were measured over various input sizes (n = 10 to 100). The Naive algorithm showed a steep increase in runtime due to its quadratic behavior (for example at n=100 the Execution time = 89.7ms), while the Optimized algorithm maintained a stable and much faster runtime (at n=100 the Execution time was only = 2.9ms).

Key Observations:
- **Speed**: The Optimized algorithm is significantly faster, especially for larger inputs.
- **Scalability**: The Naive algorithm is only practical for small n, whereas the Optimized version scales well.
- **Stability**: The Optimized version produces more predictable results, while the Naive version can generate erratic outputs due to accumulated randomness.
- **Use Case**: The Naive approach may be useful for educational or experimental scenarios, but the Optimized version is better suited for real-world applications requiring speed and consistency.

Conclusion:
The Optimized algorithm outperforms the Naive version in both theoretical and empirical results. With its linear runtime and simpler structure, it delivers more reliable and scalable predictions, making it the better choice for modern weather prediction systems.

Results Comparison

5.2 Discussion of Discrepancies

While the theoretical analysis indicated a clear performance advantage for the Optimized algorithm due to its linear time complexity (O(n) vs. O(n^2)), the experimental results further confirmed this behavior. However, minor discrepancies between expected and actual runtimes were observed during testing.
For example, even though both algorithms have a best-case time complexity of O(1), the Naive algorithm occasionally showed slightly higher runtimes for small input sizes. These variations can be attributed to:

- Nested loop overhead in the Naive algorithm, which adds more processing steps per iteration.
- System-level factors, such as background processes or task scheduling by the operating system.
- Random number generation, which introduces some variability in runtime depending on the sequence and frequency of random operations.

Since the code was implemented in C++, the results were also influenced by factors such as compiler optimizations and memory access patterns. The Optimized algorithm, with its simpler loop structure and fewer calculations per iteration, benefits from better runtime behavior and CPU efficiency.
Overall, these discrepancies are minor and expected when transitioning from theoretical models to real-world execution. The performance trends remained consistent: the Optimized algorithm was more efficient, scalable, and reliable under varying input sizes.

Conclusion

In this project, we aimed to compare two distinct approaches for weather prediction: a naive rule-based algorithm and an optimized model. The results clearly showed that while the naive algorithm works well for smaller datasets, it becomes inefficient and unrealistic as the prediction days increase. This inefficiency is due to the increasing randomness and the quadratic time complexity, which results in a significant slowdown as the number of prediction days grows.

On the other hand, the optimized algorithm demonstrated superior performance in both prediction accuracy and runtime efficiency. By using a machine learning model, we were able to handle the non-linear nature of weather data more effectively, providing more stable and reliable predictions even with larger datasets. The time complexity of the optimized model remained linear (O(n)), making it scalable and suitable for real-world applications, such as weather forecasting systems.

The empirical analysis confirmed the theoretical findings: while the naive algorithm struggled with larger input sizes, the optimized algorithm maintained consistent and faster performance. The experiments highlighted the advantages of using more sophisticated models, especially when dealing with complex data that requires accuracy and efficiency.

Throughout this project, we learned the importance of selecting the appropriate algorithm based on the problem at hand. While the naive model was simple and easy to implement, the optimized model's ability to scale and produce accurate results makes it a better choice for practical applications. The project also taught us valuable lessons in algorithmic design, complexity analysis, and empirical testing.

In real-world applications, the ability to make accurate and timely weather predictions is crucial. By improving the efficiency of predictive algorithms, industries such as agriculture, transportation, and public safety can benefit significantly. This project not only provided insights into algorithmic performance but also showcased how algorithmic improvements can have a tangible impact on decision-making in various sectors.
